Abstract

As experiment complexity in fields such as nuclear engineering continues to increase, so does the demand for robust computational methods to simulate them. In many simulations, input design parameters as well as intrinsic experiment properties are sources of input uncertainty. Often, small perturbations in uncertain parameters have significant impact on the experiment outcome. For instance, when considering nuclear fuel performance, small changes in the fuel thermal conductivity can greatly affect the maximum stress on the surrounding cladding. The difficulty of quantifying input uncertainty impact in such systems has grown with the complexity of the numerical models. Traditionally, uncertainty quantification has been approached using random sampling methods like Monte Carlo. For some models, the input parametric space and corresponding quantity-of-interest output space is sufficiently explored with a few low-cost computational calculations. For other models, it is computationally costly to obtain a good understanding of the output space.

To combat the costliness of random sampling, this research explores the possibilities of advanced methods in stochastic collocation for generalized polynomial chaos (SCgPC) as an alternative to traditional uncertainty quantification techniques such as Monte Carlo (MC) and Latin Hypercube sampling (LHS) methods. In this proposal we explore the behavior of traditional SCgPC construction strategies, as well as truncated polynomial spaces using total degree (TD) and hyperbolic cross (HC) construction strategies. We also consider applying anisotropy to the polynomial space, and analyze methods whereby the level of anisotropy can be approximated. We review and develop potential adaptive polynomial construction strategies. Finally, we add high-dimension model reduction (HDMR) expansions, using SCgPC representations for the constituent terms, and consider adaptive methods to construct them. We analyze these methods on a series of models of increasing complexity. We primarily use analytic methods of various means, and finally demonstrate on an engineering-scale neutron transport problem. For this analysis, we demonstrate the application of the algorithms discussed above in `raven`, a production-level uncertainty quantification framework.

Finally, we propose additional work in enhancing the current implementations of SCgPC and HDMR.

Chapter 1

Introduction

In simulation modeling, we attempt to capture the behavior of a physical system by describing it in a series of equations, often partial differential equations. These equations may be time-dependent, and capture physics of interest for understanding the system. A *solver* is then written that can solve the series of equations and determine quantities of interest (QoI). A traditional solver accepts a set of inputs and produces a set of single-valued outputs. For instance, a solver might solve equations related to the attenuation of a beam of photons through a material, and the QoI might be the strength of the beam exiting the material. A single run of the solver usually results in a single value, or realization, of the quantity of interest.

This single realization might be misleading, however. In most systems there is some degree of uncertainty in the input parameters to the solver. Some of these uncertainties may be epistemic, or systematic uncertainty originating with inexact measurements or measurable unknowns. Other uncertainties might be aleatoric, intrinsic uncertainty in the system itself, such as probabilistic interactions or random motion. Taken together, the input parameter uncertainties exist within a multidimensional probabilistic space. While some points in that space may be more likely than others, the possible range of values for the QoI is only understood when the uncertain input space is considered as a whole. We note here that while it is possible that some of the input parameters are correlated in their probabilistic distribution, it is also possible to decouple them into uncorrelated variables. Throughout this work we will assume the input parameters are uncorrelated.

One traditional method for exploring the uncertain input space is through random sampling, such as in analog Monte Carlo sampling. In this method, a point in the input space is chosen at random based on probability. This point represents values for the input parameters to the solver. The solver is executed with these inputs, and the QoIs

are collected. Then, another point in the input space is chosen at random. This process continues until the properties of the QoIs, or *response*, are well understood.

There are some beneficial properties to random sampling approaches like Monte Carlo. Significantly, they are unintrusive: there is no need to modify the solver in order to use these methods. This allows a framework of algorithms to be developed which know only the input space and QoI of a solver, but need no further knowledge about its operation. Unintrusive methods are desirable because the uncertainty quantification algorithms can be developed and maintained separately from the solver.

Monte Carlo and similar sampling strategies are relatively slow to converge on the response surface. For example, with Monte Carlo sampling, in order to reduce the standard error of the mean of the response by a factor of two, it is necessary to take at least four times as many samples. If a solver is sufficiently computationally inexpensive, running additional solutions is not a large concern; however, for lengthy and expensive solvers, it may not be practical to obtain sufficient realizations to obtain a clear response.

In this work, we will assume solvers are computationally expensive, requiring many hours per solve, and that computational resource availability requires as few solves as possible. As such, we consider several methodologies for quantifying the uncertainty in expensive solver calculations. In order to demonstrate clearly the function of these methods, we apply them first on several simpler problems, such as polynomial evaluations and analytic attenuation. These models have a high degree of regularity, and their analyticity provides for straightforward benchmarking. Through gradual increasing complexity, we investigate the behavior of the UQ methods.

Finally, we apply the methods to an engineering-scale solver that models the neutronics and performance of nuclear fuel. This will demonstrate the practical application of the uncertainty quantification methods, where the regularity and other properties of the model are not well understood.

The first uncertainty quantification method we consider is traditional analog Monte Carlo (MC) analysis, wherein random sampling of the input space generates a view of the response. MC is used as a benchmark methodology; if other methods converge on moments of the quantities of interest more quickly and consistently than MC, we consider them "better" for our purposes.

The second method we consider is stochastic collocation for generalized polynomial chaos (SCgPC)[11, 22–24], whereby deterministic collocation points are used to develop a polynomial-interpolated reduced-order model of the response as a function of the inputs. This method algorithmically expands the solver as the sum of orthogonal multi-dimensional polynomials with scalar coefficients. The scalar coefficients are obtained by

numerical integration using multidimensional collocation (quadrature) points. The chief distinction between SCgPC and Monte Carlo methods is that SCgPC is deterministic, in that the realizations required from the solver are predetermined instead of randomly sampled. There are two major classes of deterministic uncertainty quantification methods: intrusive and unintrusive. Like Monte Carlo, SCgPC is unintrusive and performs well without any need to access the operation of the solver. This behavior is desirable for construction black-box approach algorithms for uncertainty quantification. Other intrusive methods such as stochastic Galerkin exist [5], but require solver modification to operate. This makes them solver-dependent and undesirable for an independent uncertainty quantification framework.

The other methods we present here expand on SCgPC. First, we introduce non-tensor-product methods for determining the set of polynomial bases to use in the expansion. Because a tensor product grows exponentially with increasing cardinality of the input space, we combat this curse of dimensionality using the alternative polynomial set construction methods[13]. These bases will then be used to construct Smolyak-like sparse grids [14] to provide collocation points that in turn calculate the coefficients in the polynomial expansion. Second, we consider anisotropic sparse grids, allowing higher-order polynomials for particular input parameters. We also consider methods for obtaining weights that determine the level of anisotropic preference to give parameters, and explore the effects of a variety of anisotropic choices.

The second method group we consider is high-dimension model representation (HDMR), which correlates with Sobol decomposition [20]. This method is useful both for developing sensitivities of the quantity of interest to subsets of the input space, as well as constructing a reduced-order model itself. We demonstrate the strength of HDMR as a method to inform anisotropic sensitivity weights for SCgPC.

Finally, we consider adaptive algorithms to construct both SCgPC and HDMR expansions using second-moment convergence criteria. We analyze these for potential efficiencies and shortcomings. We also propose future work to further improve the adaptive methods.

We implement all these methods in Idaho National Laboratory's `raven`[9] uncertainty quantification framework. `raven` is a Python-written framework that non-intrusively provides tools for analysts to quantify the uncertainty in their simulations with minimal development. To demonstrate the application of the method developed, we use a complex non-linear multiphysics system solver simulating the operation of a fuel pin within a nuclear reactor core, including both neutronics and fuel performance physics kernals. For this solver, we use the coupled `rattleSNake`[10] and `bison` [6, 8] production codes. Both of these codes are developed and maintained within the `moose`[7] environment. The

multiphysics nonlinear system provides a challenge with unknown response properties for the uncertainty quantification methods discussed in this proposal.

The remainder of this work will proceed as follows:

- Chapter 2: We describe the analytic test problems and engineering-scale problem solved by the simulations we will be running, along with their properties and inferences about the algorithms developed. We discuss potential approaches to model solving and applications of the models.

- Chapter 3: We describe methods for uncertainty quantification, including Monte Carlo (MC), stochastic collocation for generalized Polynomial Chaos (SCgPC), and high-dimension model reduction (HDMR).

- Chapter 4: We analyze results obtained for the static UQ methods on analytic models, and contrast them with traditional Monte Carlo convergence on statistical moments.

- Chapter 5: We describe implementation of adaptive methods for both SCgPC and HDMR. We discuss the strengths, weaknesses, and options for these adaptive methods.

- Chapter 6: We evaluate results for the adaptive methods in comparison with static methods and Monte Carlo for the analytic models. We again consider the strengths and weaknesses of the adaptive methods in light of the results.

- Chapter 7: We perform analysis on the engineering-scale multiphysics coupled problem, and analyze results.

- Chapter 8: We draw conclusions from the evaluations performed, and offer some suggestions for applicability as well as future development for the UQ methods demonstrated.

Chapter 2

Models

2.1 Introduction to Models

In this section we present the models used in demonstrating the uncertainty quantification (UQ) methods in this work. We use the term *model* to describe any code with uncertain inputs and a set of at least one response quantity of interest. We include a variety of models with the intent to demonstrate the strengths and weaknesses of each UQ method.

Firstly, we include several analytic models. These are models who have an exact, derivable value for statistical moments or sensitivities. They are simpler in mechanics than full engineering-scale problems, and offer a way to benchmark the performance of the UQ methods.

Secondly, we include an engineering-scale multiphysics application. There are no analytic response values in this model, only a nominal case with no uncertainty included in the input space. Demonstration of the performance of UQ methods on this model will highlight the practical application of each method.

We describe each model in turn. Throughout the models, we will describe them using the syntax

$$u(Y) = Q, \tag{2.1}$$

where $u(Y)$ is the model as a function of N uncertain inputs $Y = (y_1, \dots, y_N)$ and Q is a single-valued response quantity of interest.

2.2 Tensor Monomials

The simplest model we make use of is a first-order tensor polynomial (tensor monomial) combination **??**. The mathematical expression is

$$u(Y) = \prod_{n=1}^{N} (y_n + 1). \tag{2.2}$$

For example, for $N = 3$ we have

$$u(Y) = y_1 y_2 y_3 + y_1 y_2 + y_1 y_3 + y_2 y_3 + y_1 + y_2 + y_3 + 1. \tag{2.3}$$

For this model we distribute the uncertain inputs in several ways: uniformly on [-1,1], uniformly on [0,1], and normally on $[\mu, \sigma]$. A summary of analytic statistics is given in Table 2.1.

Distribution	Mean	Variance
$\mathcal{U}[-1,1]$	1	$\left(\frac{4}{3}\right)^N - 1$
$\mathcal{U}[0,1]$	$\left(\frac{3}{4}\right)^N$	$\left(\frac{7}{3}\right)^N - \left(\frac{3}{4}\right)^{2N}$
$\mathcal{N}[\mu, \sigma]$	$\prod_{n=1}^{N}(\mu_{y_n} + 1)$	$\prod_{n=1}^{N}[(\mu_{y_n} + 1)^2 + \sigma_{y_n}^2] - \prod_{n=1}^{N}(\mu_{y_n} + 1)^2$

TABLE 2.1: Analytic Expressions for Tensor Monomial Case

2.3 Sudret polynomial

The Sudret polynomial [30] is another tensor-like polynomial, and is a test case traditionally used to identify convergence on sensitivity parameters. The mathematical expression is

$$u(Y) = \frac{1}{2^N} \prod_{n=1}^{N} (3y_n^2 + 1). \tag{2.4}$$

The variables are distributed uniformly on [0,1]. The statistical moments and sensitivities are given in Table 2.2, where $\mathcal{S}_n$ is the global Sobol sensitivity of $u(Y)$ to perturbations in y_n.

Statistic	Expression
Mean	1
Variance	$\left(\frac{6}{5}\right)^N - 1$
$\mathcal{S}_n$	$\frac{5^{-n}}{(6/5)^N - 1}$

TABLE 2.2: Analytic Expressions for Sudret Case

2.4 Attenuation

This model represents an idealized single-dimension system where an beam of particles impinges on a purely-absorbing material with total scaled length of 1. The response of interest is the fraction of particles exiting the opposite side of the material. The material is divided into N segments, each of which has a distinct uncertain absorption cross section y_n. The solution takes the form

$$u(Y) = \prod_{n=1}^{N} \exp(-y_n/N). \tag{2.5}$$

Because negative cross sections have dubious physical meaning, we restrict the distribution cases to uniform on [0,1] as well as normally-distributed on $[\mu, \sigma]$. A summary of analytic statistics is given in Table 2.3.

Distribution	Mean	Variance
$\mathcal{U}[0,1]$	$\left[N\left(1 - e^{-1/N}\right) \right]^N$	$\left[\frac{N}{2}\left(1 - e^{-2/N}\right) \right]^N - \left[N\left(1 - e^{-1/N}\right) \right]^{2N}$
$\mathcal{N}[\mu, \sigma]$	$\prod_{n=1}^{N} \exp\left[\frac{\sigma_{y_n}^2}{2N^2} - \frac{\mu_{y_n}}{N} \right]$	$\prod_{n=1}^{N} \exp\left[\frac{2\sigma_{y_n}^2}{N^2} - \frac{2\mu_{y_n}}{N} \right]$

TABLE 2.3: Analytic Expressions for Attenuation Case

This model has some interesting properties to demonstrate performance of polynomial-based UQ methods. First, because the solution is a product of exponential functions, it cannot be exactly represented by a finite number of polynomials. Second, the Taylor development of the exponential function includes all increasing polynomial orders. The product of several exponential functions is effectively a tensor combination of polynomials for each dimension.

2.5 Gaussian Peak

Similar to the attenuation model, the Gaussian peak [31] instead uses square arguments to the exponential function. A tuning parameter a can be used to change the peakedness of the function. Increased peakedness leads to more difficult polynomial representation. A location parameter μ can be used to change the location of the peak. The mathematical expression is

$$u(Y) = \exp\left(-\sum_{n=1}^{N} a^2(y_n - \mu)^2 \right). \tag{2.6}$$

We allow each y_n to vary uniformly on [0,1]. A summary of analytic statistics is given in Table 2.4.

Statistic	Expression
Mean	$\left(\frac{\sqrt{\pi}}{2a}(\text{erf}(a\mu) + \text{erf}(a - a\mu))\right)^N$
Variance	$\left(\frac{\sqrt{\pi/2}}{2a}\left(\text{erf}(a\mu\sqrt{2}) - \text{erf}(a\sqrt{2}(1-\mu))\right)\right)^N - \left(\frac{\sqrt{\pi}}{2a}(\text{erf}(a\mu) + \text{erf}(a - a\mu))\right)^{2N}$

TABLE 2.4: Analytic Expressions for Gaussian Peak Case

This case offers particular challenge because of its Taylor development, which only includes even powers of the uncertain parameters. This suggests added difficulty in successive representation, especially for an adaptive algorithm.

2.6 Ishigami Function

The Ishigami function [32] is a commonly-used function in performing sensitivity analysis. It is given by

$$u(Y) = \sin y_1 + a \sin^2 y_2 + b y_3^4 \sin(y_1). \tag{2.7}$$

In our case, we will use $a = 7$ and $b = 0.1$ as in [33]. In particular interest for this model are its strong nonlinearity and lack of independence for y_3, as it only appears in conjunction with y_1. The analytic statistics of interest for this model are in Table 2.5, where D_n is the partial variance contributed by y_n and Sobol sensitivities $\mathcal{S}_n$ are obtained by dividing D_n by the total variance.

| Statistic	Expression	Approx. Value
Mean	$\frac{7}{2}$	3.5
Variance	$\frac{a^2}{8} + \frac{b\pi^4}{5} + \frac{b^2\pi^8}{18} + \frac{1}{2}$	13.84459
D_1	$\frac{b\pi^4}{5} + \frac{b^2\pi^8}{50} + \frac{1}{2}$	4.34589
D_2	$\frac{a^2}{8}$	6.125
$D_{1,3}$	$\frac{8b^2\pi^8}{225}$	3.3737
$D_3, D_{1,2}, D_{2,3}, D_{1,2,3}$	0	0

TABLE 2.5: Analytic Expressions for Ishigami Case

2.7 Pin Cell

This model is a coupled multiphysics engineering-scale model. It simulates fuel behavior through the depletion of fissile material in a single two-dimensional slice of a fuel rod. The problem domain contains the fuel, gap, clad, and moderator, and represents a symmetric quarter pin. The depletion steps are carried out through a year-long burn

cycle. The coupled multiphysics are neutronics, handled by `rattleSNake`, and fuel performance, handled by `bison`.

The mesh is shown in Fig. **??**. TODO BETTER FIGURE. The mesh contains 20 bands of fuel blocks, the gap, the clad, and the moderator. TODO Use colors to describe locations. TODO dimensions.
The neutronics is calculated using 8 energy groups and takes as uncertain inputs 671 material cross sections, including fission, capture, scattering, and neutron multiplication factor Each cross section is perturbed by 10% of its original value, distributed normally. The scattering cross sections for each material in each group are not perturbed individually; rather, a scattering scaling factor for each group is determined, and the scattering cross sections are all scaled by that factor. The fission and capture cross sections are perturbed individually. The critical output of the neutronics calculation is power shapes for use in the fuel performance code, as well as the k-eigenvalue for the rod.

The fuel performance code models mechanics such as heat conduction in the fuel, clad, and gap, clad stresses, grain radius growth, and fuel expansion through the depletion steps of the fuel. The code takes power shapes from the neutronics code as input and produces several key characteristics, such as peak clad temperature, maximum fuel centerline temperature, and maximum clad stress.

The uncertain input space is highly correlated, so a Karhunen-Loeve (KL) component analysis is performed as the first step in a two-part reduction [28]. The covariance matrix is obtained via cross section construction in `scale`[29] using random sampling. Table 2.6 gives the first several eigenvalues in the KL expansion. Surrogate (or *latent*) dimensions

identified by the KL expansion will be used as input variables for demonstration of the various UQ methods.
